RESEARCH LETTER

10.1029/2019GL081964

Key Points:

- MMS observes a long-lasting large-amplitude electromagnetic ion cyclotron wave event in the dawnside flank of the magnetosheath
- Density fluctuations are both positively and negatively correlated with the parallel magnetic field
- Local excitation of the electromagnetic ion cyclotron instability and mirror instability contributes to the observed fluctuations

Abstract The electromagnetic ion cyclotron (EMIC) wave usually observed in the Earth's magnetosheath is thought to be generated through the ion temperature anisotropy instability. This paper presents an observation of a long-lasting large-amplitude EMIC wave event in the dawnside flank of the magnetosheath by the Magnetospheric Multiscale mission, lasting from 06:33:00 to 12:35:00 UT on 16 April 2018. The wave amplitude is around 0.2 nT as compared to the ambient magnetic field ~12 nT. The characteristic frequency and scale size are around 0.2 Hz and 1,028 km, respectively. Accompanying EMIC waves are density fluctuations, which exhibit both positive and negative correlations with the longitudinal magnetic field. Using the fitted parameters for the ion and electron phase space densities, plasma kinetic theory predicts local excitations of both EMIC and mirror instabilities, which provide the energy of these observed EMIC waves and density fluctuations.

Plain Language Summary The Earth's Magnetosheath is a region slowing down high-speed particles originating from the solar wind, protecting the Earth from the hazards of high-energy charged particles. A considerable fraction of the energy of energetic particles is transferred into plasma waves. This paper presents an observational event of large-amplitude low-frequency electromagnetic waves lasting nearly 6 hr, propagating from the outer magnetosheath to the inner magnetosheath. Density fluctuations are found to coexist with these electromagnetic waves. Applying the measurements of charged particles to modeling, we show the observed waves are likely excited by free energy provided by ions with an anisotropic temperature distribution, consistent with wave theory.

1. Introduction

The Earth's magnetosheath is a region between the Earth's bow shock and magnetopause (Lucek et al., 2005). A considerable fraction of the plasma bulk flow energy in the solar wind is converted into the plasma thermal energy in the magnetosheath, where the plasma temperature perpendicular to the magnetic field T_{\perp} is usually larger than the parallel temperature T_{\parallel} (Lucek et al., 2005; Sckopke et al., 1990). A large ion temperature anisotropy with $T_{\perp} > T_{\parallel}$ can also be developed in the plasma depletion layer nearby the magnetopause (e.g., Anderson et al., 1991; Zwan & Wolf, 1976). This temperature anisotropy can trigger the ion cyclotron anisotropy instability and the mirror instability, producing the electromagnetic ion cyclotron (EMIC) wave and the mirror wave (Gary, 1992; Gary et al., 1993). Under the assumptions of a uniform plasma and a bi-Maxwellian ion velocity distribution, the EMIC instability has a nonzero real frequency and maximum growth at propagation parallel to the background magnetic field B_0 , whereas the ion mirror instability has a zero real frequency and maximum growth rate at propagation oblique to B_0 (Gary, 1993). These two wave modes are frequently observed in the magnetosheath (e.g., Anderson et al., 1994; Czaykowska et al., 1998; Denton et al., 1994; Hubert et al., 1989; Lacombe et al., 1992; Sckopke et al., 1990; Tsurutani et al., 1982, 2011), especially downstream of the quasi-perpendicular bow shock (e.g., Schwartz et al., 1996).

EMIC waves observed in the magnetosheath can have large amplitude. For example, shortly after crossing of the quasi-perpendicular shock, EMIC waves having amplitude ~10 nT were found by the Cluster satellites,

propagating along the downstream magnetic field where $B_0 \sim 90$ nT (Alexandrova et al., 2004). Cassini and Wind spacecraft measurements have shown the existence of large-amplitude EMIC waves in the duskside flank of the magnetosheath where the peak amplitude is ~ 4 nT and $B_0 \sim 25$ nT, and in the subsolar magnetosheath where the peak amplitude is about 14 nT compared with $B_0 \sim 55$ nT (Remya et al., 2014). Furthermore, a statistical analysis from AMPTE/IRM spacecraft proposed that EMIC waves contribute mainly to electromagnetic fluctuations downstream of the quasi-perpendicular low-beta shocks and the average relative amplitude $\delta B/B_0$ is around 0.08 (Czaykowska et al., 2001). Recently, Zhao et al. (2018) applied the NASA Magnetospheric Multiscale (MMS) mission's high temporal resolution plasma measurements to show modulation of ion and electron pitch angle distribution in the presence of large-amplitude EMIC waves. These large-amplitude EMIC waves may play important roles in triggering nonlinear instability and scattering of ions in the magnetosheath (i.e., Alexandrova et al., 2004; Kitamura et al., 2018; McKean et al., 1995).

In addition to large-amplitude EMIC waves, EMIC waves have also been reported to occur simultaneously with plasma density fluctuations (Lacombe et al., 1995). However, the mechanism responsible for these density fluctuations still remains unknown. Using data from the MMS mission, this paper presents observational evidences of the coexistence of both large-amplitude EMIC waves and density fluctuations. Through the analyses of the observed wave characteristics, in combination with the linear instability predictions from plasma kinetic theory, we propose that the EMIC instability is responsible for EMIC waves, and both EMIC and mirror instabilities contribute to density fluctuations.

2. Data Set

This study analyzes the wave activity from electromagnetic field and plasma data of the MMS mission. Magnetic field measurements by the FluxGate Magnetometer (FGM) provide the magnetic field data with the temporal resolution of 16 samples per second in survey mode and 128 samples per second in burst mode (Russell et al., 2016). We use the electric field data with a sample rate of 32 Hz from the Electric Double Probes (Ergun et al., 2016; Lindqvist et al., 2016). Plasma measurements by the Fast Plasma Investigation (FPI) provide plasma data with the cadence of 4.5 s in fast mode and the cadences 150 ms for ions and 30 ms for electrons in burst mode (Pollock et al., 2016). Since the Dual Ion Spectrometer in FPI is unable to discriminate protons from other kinds of ion species, we assume all ions detected by Dual Ion Spectrometer/FPI contributed by protons. The density and temperature of ion species of He^+ , He^{++} , and O^+ are obtained from the Hot Plasma Composition Analyzer (Young et al., 2016).

3. Plasma Overview and Wave Observations

The MMS spacecraft detects an EMIC wave event during the interval of 06:33:00–12:35:00 UT on 16 April 2018. As illustrated in the MMS1 trajectory (Figures 1h and 1i), the spacecraft is located in the dawnside flank region of the magnetosheath. It moves from $(-3.62, -20.52, 6.31) R_E$ at 06:33:00 UT to $(-2.19, -22.79, 7.09) R_E$ at 12:35:00 UT. During this interval, the interplanetary magnetic field in GSE coordinates is $\mathbf{B}_{\text{GSE}} \approx (-1.8, -3.5, 0.6)$ nT, indicating the event is located downstream of the quasi-perpendicular bow shock. An overview of plasma and magnetic field is presented in Figures 1a–1g. Both plasma and magnetic field stay almost stable. During the prolonged interval of 09:55:00–11:20:00 UT, the time-averaged plasma parameters are $n_i \approx 28.1 \text{ cm}^{-3}$, $T_i \approx 76.9 \text{ eV}$, $T_e \approx 23.6 \text{ eV}$, $B_0 \approx 11.5 \text{ nT}$, Alfvén speed $V_A = B_0/\sqrt{\mu_0 m_i n_i} \approx 47.2 \text{ km/s}$, and ion bulk flow speed $\mathbf{V}_{\text{GSE}} \approx (-206.0, -73.9, 41.6) \text{ km/s}$ with an angle of $\sim 22.7^\circ$ with respect to the mean magnetic field. As labeled by the two dashed vertical lines in Figures 1a–1g, the burst mode continually operates during 10:23:14–10:58:32 UT, which provides a high temporal resolution data set supporting detailed analysis of plasma fluctuations.

Figure 2a presents the power spectral densities (PSDs) of the magnetic field, ion and electron velocity, and ion and electron number density by using Welch's method (Welch, 1967). Before calculating these PSDs, magnetic field data in burst mode (128 samples per second) are smoothly averaged over a time interval of 1,000 s, which are used as the background magnetic field. We then transform magnetic field and velocity vector data from GSE coordinates to a mean-field aligned coordinate system where three axes are defined as $\mathbf{e}_{\perp 1} = \mathbf{e}_{\perp 2} \times \mathbf{e}_{\parallel}$, $\mathbf{e}_{\perp 2} = \mathbf{e}_{\parallel} \times \mathbf{R}/R$, and $\mathbf{e}_{\parallel} = \mathbf{B}_0/B_0$ and \mathbf{R} is the position vector of MMS1. Here and throughout this paper the terms “perpendicular” and “parallel” refer to directions with respect to B_0 .

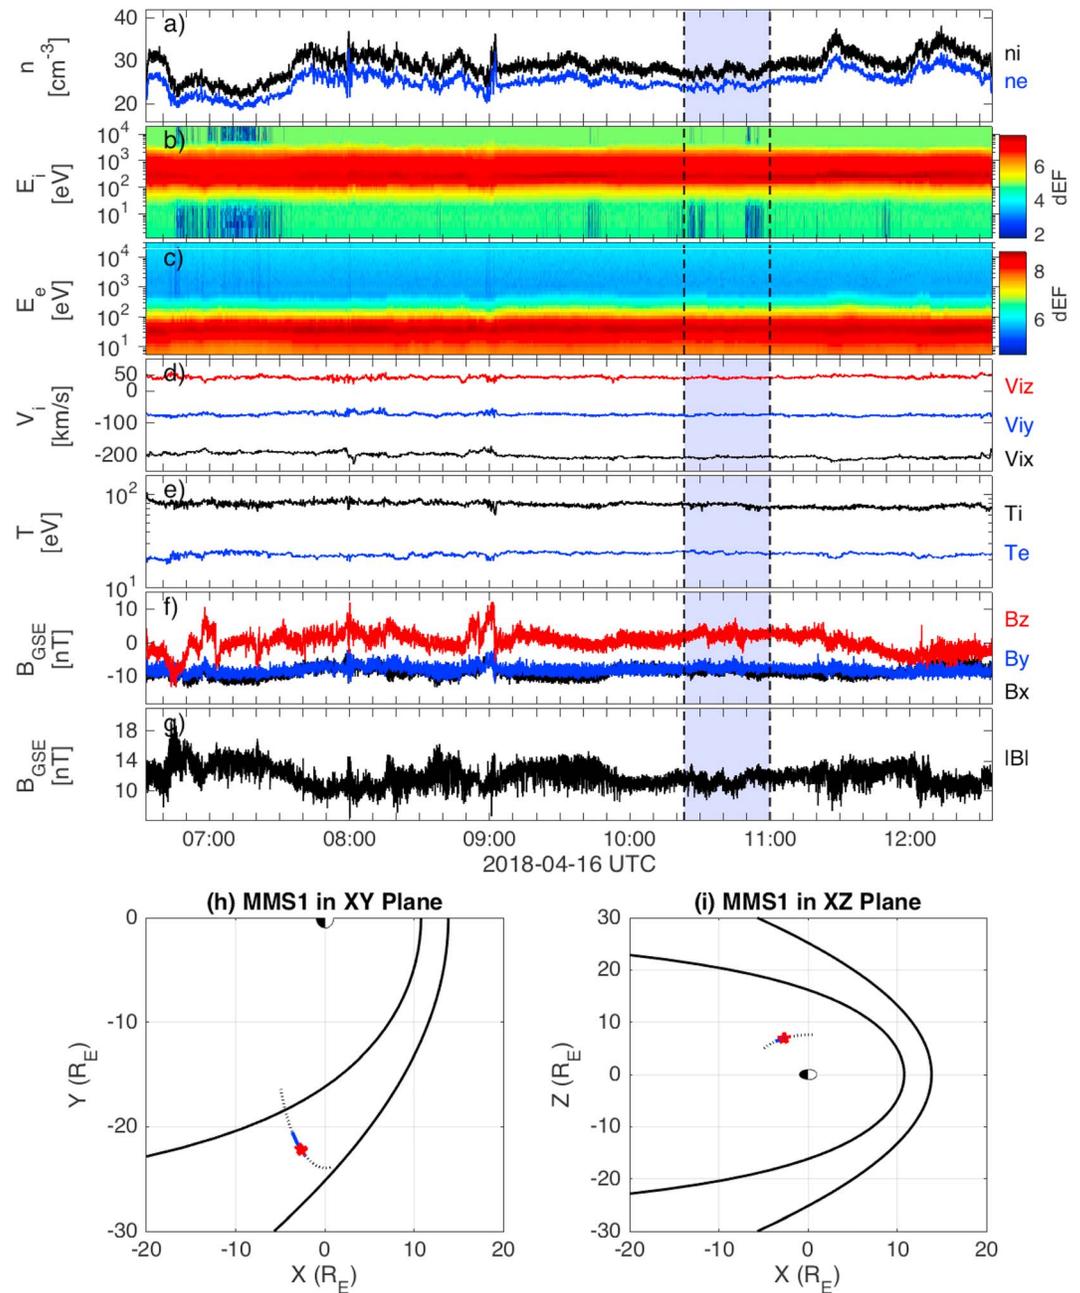

Figure 1. Overview for the plasma and magnetic field measurements from MMS1 during 06:33:00–12:35:00 on 16 April 2018. (a) The ion and electron density; (b) the ion spectrogram of differential energy flux; (c) the electron spectrogram of differential energy flux; (d) the ion bulk velocity; (e) the ion and electron temperature; (f) the magnetic field in GSE coordinates; and (g) the total magnetic field. The MMS1 trajectory in XY and XZ planes in GSE coordinates is shown in panels (h) and (i), where the dotted and dashed lines correspond to the time interval of 00:00:01–23:59:59 and 06:33:00–12:35:00 on 16 April 2018. The burst mode continually operates in the time interval of 10:23:14–10:58:32 UT, labeled by two dashed lines in panels (a)–(g) and by the red stars in panels (h)–(i).

The PSDs of perpendicular magnetic field components exhibit remarkable enhancements in the range of 0.1–1 Hz, nearly at and above the local proton cyclotron frequency $f_{cp} \approx 0.17$ Hz, whereas the PSD of the parallel magnetic field in the range of 0.1–1 Hz is roughly an order of magnitude lower than the perpendicular magnetic field PSDs. The PSDs of perpendicular ion and electron velocities are also enhanced in 0.1–1 Hz. Since the frequencies of these enhanced perpendicular fluctuations are smaller than the Doppler shifted frequency $f_{\lambda_p} = V_{i||}/\lambda_p \approx 5$ Hz at the proton inertial length λ_p (estimated from

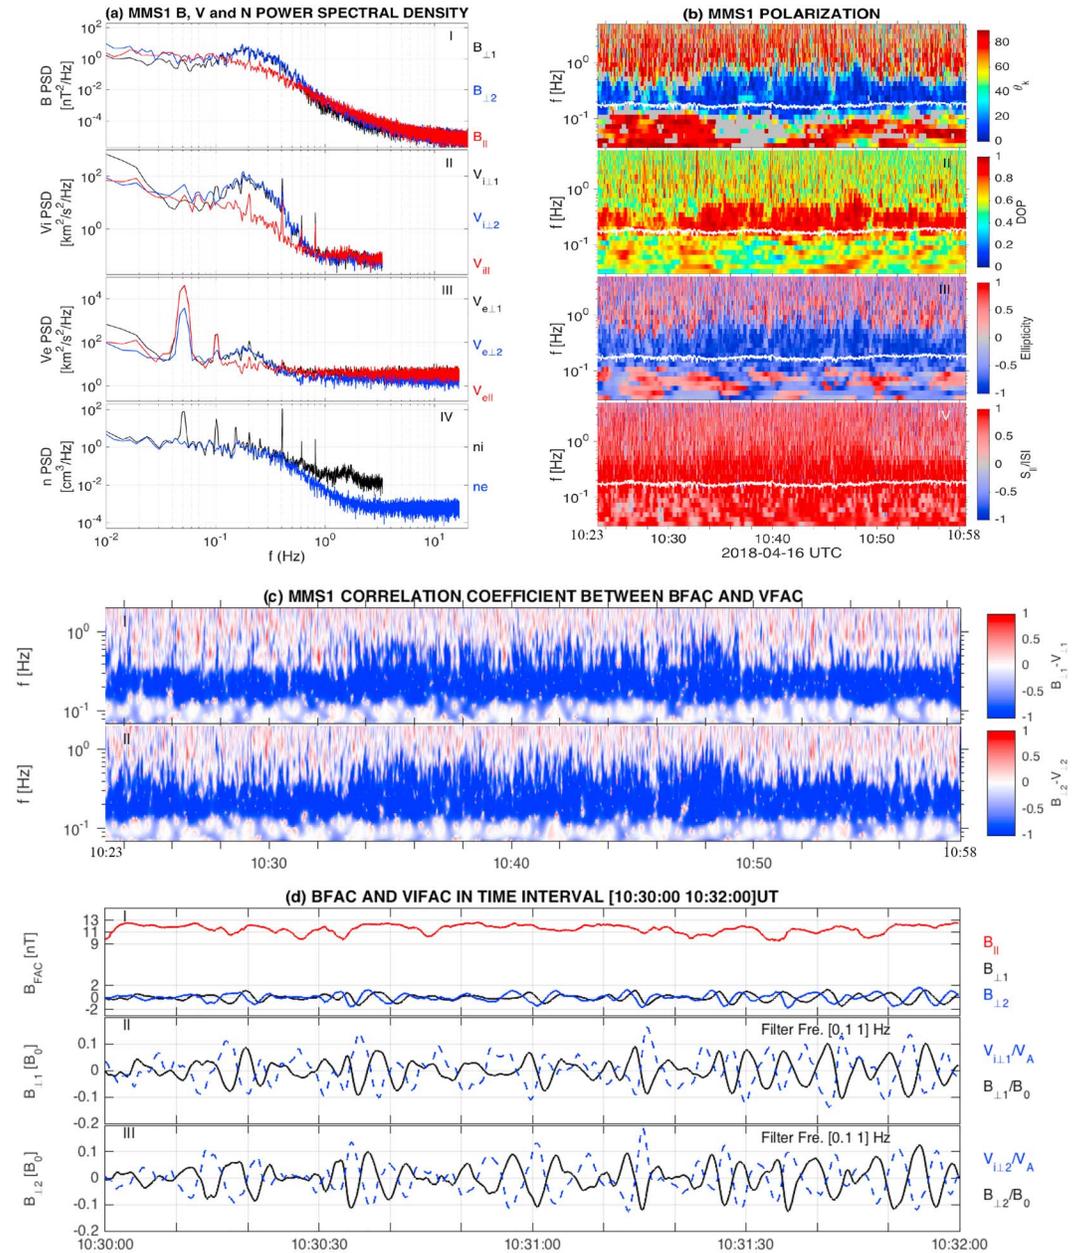

Figure 2. (a) Power spectral density (PSD) of the magnetic field (panel I), ion velocity (panel II), electron velocity (panel III), and ion and electron number density (panel IV) during 10:23:14–10:58:32 UT. (b) Polarization analysis at 0.02–5 Hz: the wave normal angle of the wave vector relative to B_0 (θ_k , panel I), the degree of polarization (DOP, panel II), the ellipticity (panel III), and the Poynting flux along the magnetic field ($S_{||}/|S|$, panel IV), where the white solid line represents the proton cyclotron frequency. (c) Correlation coefficients of $B_{\perp 1}$ and $V_{i \perp 1}$ (panel I) and of $B_{\perp 2}$ and $V_{i \perp 2}$ (panel II). (d) An example for the magnetic field and ion velocity in FAC during 10:30:00–10:32:00 UT, where the solid and dashed lines represent the magnetic field and ion velocity components, respectively.

$V_{i||} \sim 205.5$ km/s and $\lambda_p \equiv \sqrt{m_p / \mu_0 n_p e^2} \sim 40$ km), their scale sizes are larger than λ_p . The PSD of the ion number density nearly matches the PSD of the electron density at $f < 0.5$ Hz and is larger than the electron density PSD at $f > 0.5$ Hz. We also notice a peak in ion density PSD between 1 and 2 Hz, whereas there is no such signature in the PSDs of the magnetic field and velocity. Moreover, several spikes are found at certain frequencies $f \simeq$ (0.4 Hz, 0.6 Hz, 0.8 Hz) in the V_i PSD (Figure 2a-II) and at $f \simeq$ (0.05 Hz, 0.1 Hz, 0.15 Hz, 0.2 Hz, 0.25 Hz) in the V_e PSD (Figure 2a-III). The spikes at these frequencies

are also seen in the PSD of the ion density (Figure 2a-IV). These periodic signatures may be a result of a spacecraft spin effect, and not due to a local physical process.

Figure 2b presents the polarization analysis of the waves based on the singular value decomposition method (e.g., Lee & Angelopoulos, 2014; Li et al., 2013; Santolík et al., 2003). It shows clear monochromatic wave signatures between 0.1 and 1 Hz, and the waves have small normal angles ($\lesssim 20^\circ$), strong degree of polarization ($\gtrsim 0.8$), and left-handed ellipticity near -0.75 . These features indicate the observed waves are consistent with left-handed quasi-field aligned EMIC waves. Since the phase speeds of EMIC waves ($V_{ph} \sim V_A \approx 47.2$ km/s) are much smaller than the parallel bulk flow velocity $V_{i\parallel}$, the Taylor assumption, $f \approx V_{i\parallel}/\lambda$, can be used to estimate the wavelength λ of EMIC waves. For $f \sim 0.2$ Hz (corresponding to the peak in the B_{\perp} PSD, Figure 2a-I), λ is approximately 1,028 km.

Figure 2c shows the correlation coefficient between B_{\perp} and $V_{i\perp}$ using the wavelet coherence technique (Grinsted et al., 2004). The correlation coefficient CC_{ij} is defined as $CC_{ij} = R_{ij}^2 \cos(\phi_{ij})$, where R_{ij}^2 and ϕ_{ij} are the coherency and phase difference angle of two signals “ i ” and “ j ” (Grinsted et al., 2004). Here the background magnetic field is chosen as running averages of magnetic field data over 10 s, not 1,000 s performed in Figure 2a. It can give a more precise estimation of the mean magnetic field for EMIC waves with the time scale smaller than 10 s. Strong anticorrelation ($C_{B_{\perp}, V_{i\perp}} \lesssim -0.85$) arises for B_{\perp} and $V_{i\perp}$ components in the range of 0.1–1 Hz. Furthermore, Figure 2d presents an example of the magnetic field and ion velocity during 10:30:00–10:32:00 UT. $B_{\perp 2}$ is nearly $\pi/2$ out of phase with $B_{\perp 1}$ (Figure 2d-I). The two B_{\perp} components in the 0.1- to 1-Hz range are anticorrelated with the corresponding $V_{i\perp}$ component, and the amplitude of the normalized magnetic field B_{\perp}/B_0 nearly equals the amplitude of the normalized ion velocity $V_{i\perp}/V_A$ (Figures 2d-II and 2d-III). These relations between B_{\perp} and $V_{i\perp}$ further identify the existence of left-hand EMIC waves.

Figure 3a presents the coherence coefficients $CC_{B_{\parallel}n}$ and $CC_{B_{\parallel}V_{\parallel}}$ during 10:23:14–10:58:32 UT. Since the ion density PSD contains sharp peaks likely resulting from a spacecraft spin effect, we use the electron density to calculate $CC_{B_{\parallel}n}$. The positive $CC_{B_{\parallel}n}$ noticeably dominates in the interval of $\sim 10:34:00$ – $10:50:00$ UT (Figure 3a-I). This positive $CC_{B_{\parallel}n}$ is suggested as a result of EMIC waves mixed with low-frequency cutoff mode (Lacombe et al., 1995). During the interval of $\sim 10:27:00$ – $10:33:00$ UT, the negative $CC_{B_{\parallel}n}$ is dominant (Figure 3a-I), even at $f > 1$ Hz. On the other hand, B_{\parallel} and V_{\parallel} are anticorrelated (Figure 3a-II), and a correlation coefficient $C_{B_{\parallel}, V_{\parallel}} < -0.55$ is seen in a number of filamentary regions. An example for B_{\parallel} , V_{\parallel} , and n during 10:30:00–10:32:00 UT is presented in Figure 3b. At $f < 0.1$ Hz, a mixture of anticorrelation, positive correlation, and $\pi/2$ out of phase of B_{\parallel} with respect to n is found in Figure 3b-III, whereas for $0.1 \text{ Hz} < f < 1 \text{ Hz}$, anticorrelation is dominant in Figure 3b-V. B_{\parallel} and V_{\parallel} are mostly anticorrelated, as shown in Figures 3b-IV and 3b-VI. Weak positive correlation between B_{\parallel} and V_{\parallel} still arises, especially at $f > 1$ Hz (Figure 3b-VI). Note that Figure 3b only exhibits an example of anticorrelation of B_{\parallel} with n . If we choose a different time interval, positive correlation between B_{\parallel} and n would appear in filamentary regions with $C_{B_{\parallel}, V_{\parallel}} < 0$ and $0.1 \text{ Hz} < f < 1 \text{ Hz}$.

4. Wave Excitation Mechanism: Instability Analysis

Our observations identify large-amplitude EMIC waves and density fluctuations with scales larger than the proton inertial length. For theoretical study on their excitation mechanism, we need to analyze the ion and electron dynamics accompanying the wave. However, as shown in Figure 1a, compared to the ion density, the electron density is underestimated, $n_e < n_i$, and this is likely due to a part of low-energy electrons not being detected by the FPI electron detector whose lowest energy channel is ~ 7 eV. Therefore, we use the ion density as the total plasma density, $n_0 = n_i$. The ion f_i and electron f_e phase space densities are presented in Figures S1 and S2 in the supporting information. A sum of five drifting bi-Maxwellian proton (electron) components is used to fit f_i (f_e). The fitted parameters are summarized in the supporting information. These fitted parameters ensure zero total charge, $\sum_j n_{pj} = \sum_j n_{ej} = n_0 = 26.86 \text{ cm}^{-3}$, and zero total current, $J_0 = e(\sum_j n_{pj} \mathbf{V}_{pdj} - \sum_j n_{ej} \mathbf{V}_{edj}) = 0$.

Using the fitted parameters and $B_0 = 11.5$ nT for modeling, we numerically solved the plasma kinetic model (Xie & Xiao, 2016) and show the theoretical predictions in Figure 4. Here the wave vector is defined as

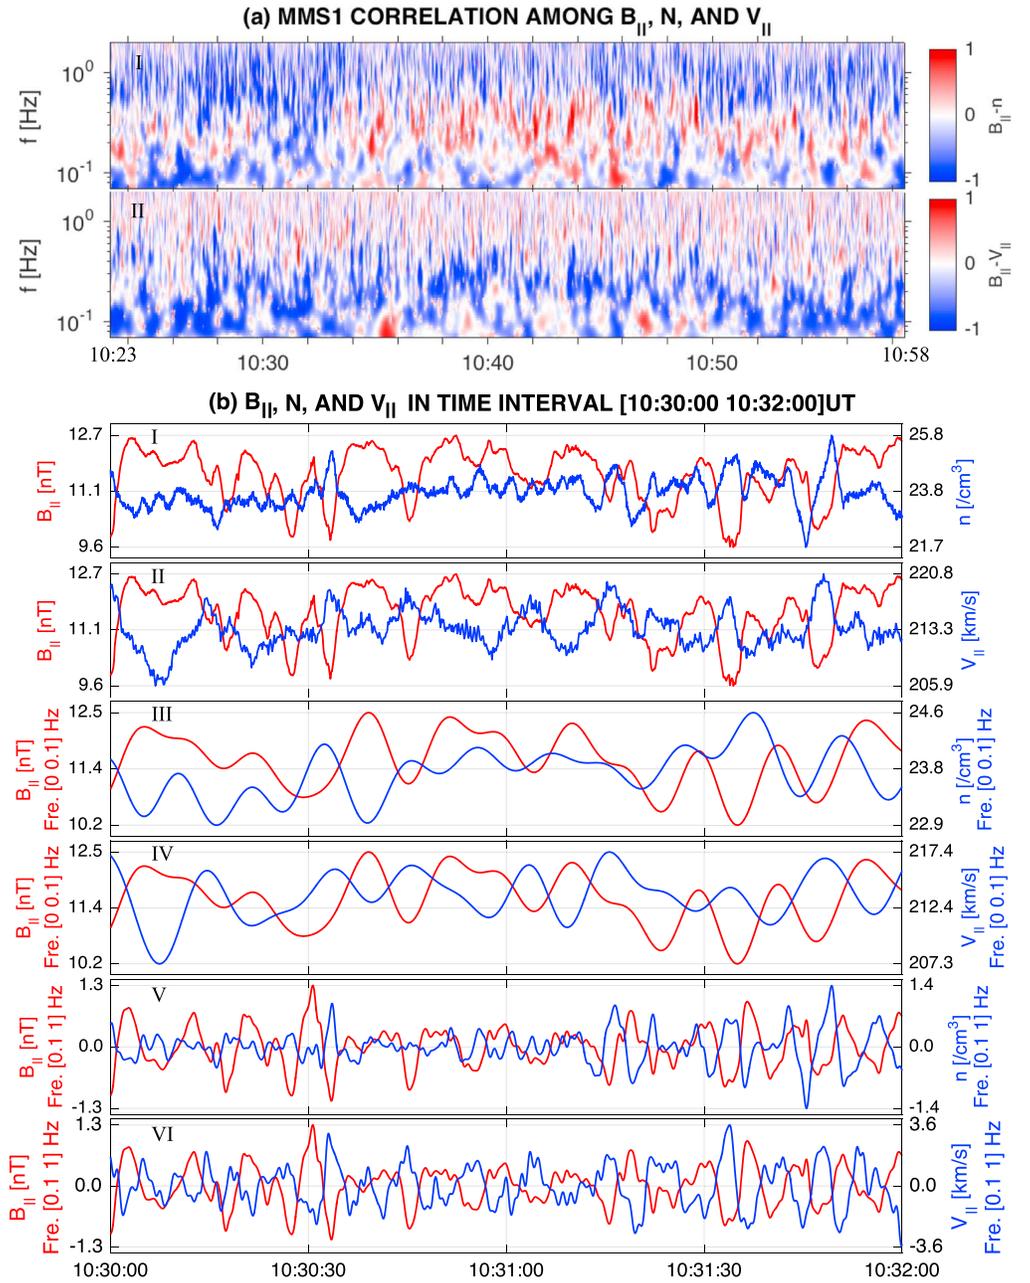

Figure 3. (a) Correlation of the parallel magnetic field $B_{||}$ to the electron density n (panel I) and to the parallel ion velocity $V_{||}$ (panel II). (b) $B_{||}$, $V_{||}$, and n during 10:30:00–10:32:00 UT: $B_{||}$ and n (panel I), $V_{||}$ and n (panel II), $B_{||}$ and n filtered in the range 0–0.1 Hz (panel III), $V_{||}$ and n filtered in 0–0.1 Hz (panel IV), $B_{||}$ and n filtered in 0.1–1 Hz (panel V), and $V_{||}$ and n filtered in 0.1–1 Hz (panel VI).

$\mathbf{k} = k_x \mathbf{e}_x + k_z \mathbf{e}_z$, where $\mathbf{e}_x \equiv \mathbf{B}_0 \times (\mathbf{k} \times \mathbf{B}_0) / |\mathbf{B}_0 \times (\mathbf{k} \times \mathbf{B}_0)|$ and $\mathbf{e}_z \equiv \mathbf{B}_0 / B_0$. As shown in Figures 4a and 4b, the theory predicts two distinct instability distributions: a nearly parallel distribution at $\theta \sim < 40^\circ$ with maximum γ_i appearing at $\theta = 0^\circ$ ($\gamma_i \simeq 0.15 f_{cp}$ and $f \simeq 2.80 f_{cp}$, labeled by point “A”), and an oblique distribution at $\theta \sim > 30^\circ$ with maximum γ_i appearing at $\theta \simeq 62^\circ$ ($\gamma_i \simeq 0.12 f_{cp}$, and $f \simeq 0.97 f_{cp}$, labeled by point “B”). The strong excitation $\gamma_i > 0.1 f_{cp}$ occurs in the wavelength range $1/\lambda \sim 0.05/\lambda_p - 0.12/\lambda_p$.

Figure 4c and 4d show all unstable modes at points A and B, respectively. At point A, the strongest instability (the red line) produces the left-hand circularly polarized EMIC mode wave. The other two

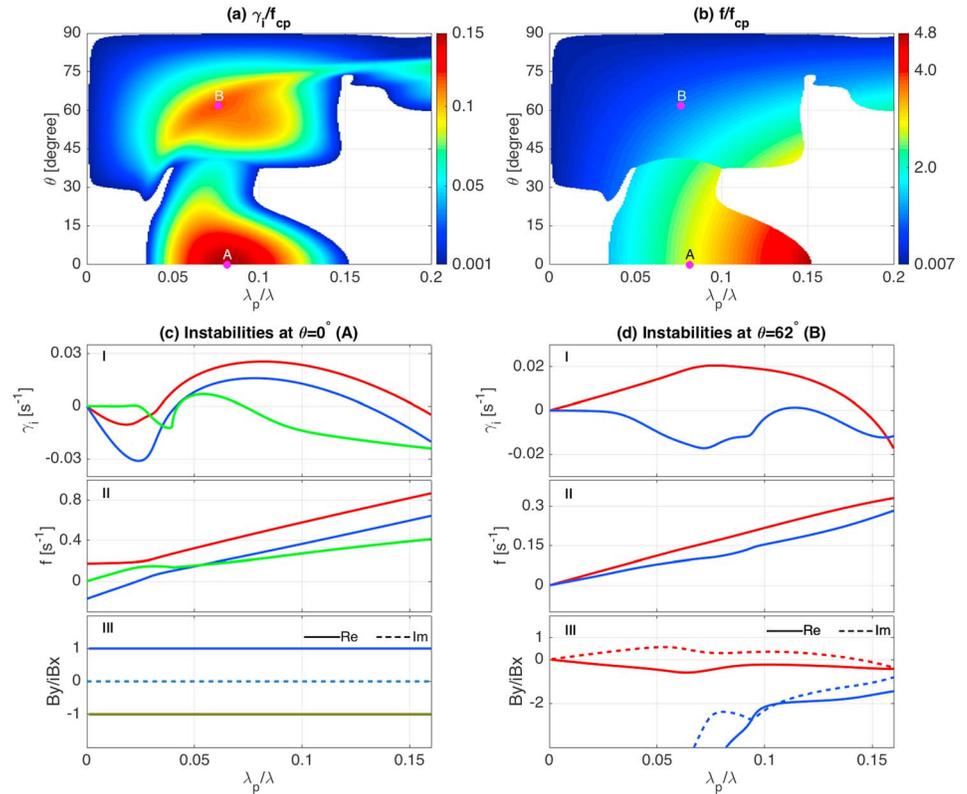

Figure 4. Linear instabilities by using the fitted plasma parameters from 10:31:00 to 10:32:00 UT. (a) Maximum growth rate γ_i as functions of the wave angle θ and the wavelength λ . (b) The wave frequency f at positions of γ_i . (c) The growth/damping rate γ_i , real frequency f , and B_y/iB_x at $\theta = 0^\circ$. (d) γ_i , f , and B_y/iB_x at $\theta = 62^\circ$. In panels for B_y/iB_x , the solid and dashed lines represent the real and imaginary part of B_y/iB_x . Points A and B denote the position of maximum value in the nearly parallel and oblique instability distributions. The growth rates in descending order are labeled by the red, blue, and green lines.

weak instabilities, shown by the blue and green lines, are caused by the proton anisotropic cyclotron instability and proton-proton beam instability. The proton beam-driven growing mode (the green line) is left-hand polarized, and its frequency is lower than the frequencies of unstable EMIC modes (the red line). At point B, the strongest growth rate (the red line) exhibits a complex polarization feature, that is, $\text{Re}(B_y/iB_x) \neq 0$ and $\text{Im}(B_y/iB_x) \neq 0$, which cannot be simply classified into left-hand $B_y/iB_x < 0$ or right-hand $B_y/iB_x > 0$. This instability corresponds to the mirror instability. We note that streaming protons would affect wave amplification and the dispersion relation of both EMIC and mirror instabilities. For example, they may cause asymmetry of the growth rate of unstable EMIC waves at directions of along and counter to B_0 and lead to a nonzero real frequency for mirror mode waves in the plasma frame. We show these as Figures S4 and S5. We also stress that this event actually contains a small population of alpha particles ($n_\alpha \approx 0.39 \text{ cm}^{-3}$) as shown in Figure S6, and these particles could result in a weak instability for lower frequency EMIC waves ($f < 0.1 \text{ Hz}$), and slightly weaken the strongest EMIC instability (see Figure S7) compared to the corresponding instability in Figure 4.

From Figures 4 and S3–S5, we believe that the EMIC instability contributes to the observed EMIC waves. The predicted wavelengths in the region of $\gamma_i > 0.1 f_{cp}$ are around 366–878 km, approximately the observed characteristic scale. The predicted maximum growth rate $\gamma_{i\text{max}}$ at $\theta = 0^\circ$ occurs at $f \approx 0.49 \text{ Hz}$, near the observed frequency of EMIC waves. In addition, the mirror instability occurring at $\theta = 62^\circ$ has $\gamma_{i\text{max}}$ slightly smaller than that predicted for the EMIC instability, and the real frequency at $\gamma_{i\text{max}}$ is nearly 0.17 Hz. The mirror instability should also be triggered under the same plasma environment, and thus, the mirror mode may contribute to density fluctuations.

5. Discussion and Summary

This study presents clear observations of large-amplitude EMIC waves in the dawnside flank of the Earth's magnetosheath. Modeling shows strong temperature anisotropies of the major ion components are capable of rendering EMIC waves unstable, suggesting the waves observed by MMS were locally generated. Also, $\gamma_i > 0.1f_{cp}$ in the EMIC instability model corresponds to the excitation of EMIC waves with normal angles smaller than 20° (Figure 4a). EMIC waves propagating at $\theta \neq 0^\circ$ are not exactly circularly polarized, and the mixing of EMIC waves at $\theta \neq 0^\circ$ with the waves at $\theta = 0^\circ$ would result in the ellipticity deviating from -1 (Denton et al., 1996).

Density fluctuations n during 10:23:14–10:58:32 UT are likely caused by both EMIC and mirror mode waves. n in the range of $0.1 \text{ Hz} < f < 1 \text{ Hz}$ is both positively and negatively correlated with B_{\parallel} . Positive correlation between n and B_{\parallel} is proposed to be partly contributed by nearly parallel EMIC waves (Lacombe et al., 1995). One may think of the fast magnetosonic wave for explaining this positive correlation. The fast wave is excluded due to two facts: (1) We do not detect any signal for right-handed polarized fast mode waves in the polarization analysis for electromagnetic waves with $0.1 \text{ Hz} < f < 1 \text{ Hz}$ (Figure 2b), and (2) the predictions of linear instability do not support excitation of the fast mode. On the other hand, negative correlation of n and B_{\parallel} can result from the slow magnetosonic wave and/or the mirror mode. Although negative correlation between B_{\parallel} and n (V_{\parallel}) is consistent with the theoretical predictions of the oblique slow magnetosonic wave (Zhang et al., 2018), we do not find a linear instability solution for the slow wave in the plasma kinetic model, nor do we observe a signature of the resonant condition for the slow wave being nonlinearly generated by large-amplitude EMIC waves (Hollweg, 1994; Wong & Goldstein, 1986). Therefore, the mirror mode is the most likely explanation for negative correlation between n and B_{\parallel} . Furthermore, linear kinetic theory also supports triggering of the mirror instability.

The mixing of both EMIC and mirror mode waves is also supported by previous magnetosheath observations and simulations (e.g., Hubert et al., 1998; McKean et al., 1995; Narita & Glassmeier, 2005). Furthermore, electromagnetic and density fluctuations in our event are propagating toward the magnetopause in the flank of the magnetosheath. When EMIC waves propagate from the position R1 (at 12:35:00 UT, in the outer magnetosheath) to the position R2 (at 06:33:00 UT, in the inner magnetosheath), the travel distance L is $L = R1 - R2 \sim 1.4 \times 10^4 \text{ km}$, and the travel time T is $T = L/V_0 \sim 60 \text{ s}$. If EMIC waves are linearly growing, the wave amplitude at R2 should be $e^{\gamma_i T} \sim 4\text{--}5$ times of the amplitude at R1. However, observations show that the amplitude near R2 ($\sim 2 \text{ nT}$) is similar to the one near R1. Hence, the observed waves remain saturation.
